Thin films of Cu<sub>2</sub>S grown by pulsed-chemical vapor deposition of bis(*N,N'*-di-*sec*-butylacetamidinato)dicopper(I) and hydrogen sulfide were converted to CuBr upon exposure to anhydrous hydrogen bromide. X-ray diffraction shows that the as-deposited films have a polycrystalline Cu<sub>2</sub>S structure. After exposure to HBr gas, the surface of the films is transformed to a  $\gamma$ -CuBr polycrystalline structure. Scanning electron microscopy and X-ray photoelectron spectroscopy reveal complete conversion of up to 100 nm of film. However, when the conversion to CuBr approaches the interface between as-

deposited Cu<sub>2</sub>S and the SiO<sub>2</sub> substrate, the morphology of the film changes from continuous and nanocrystalline to sparse and microcrystalline.

## I. INTRODUCTION

Research into photovoltaics employing a perovskite absorber layer (formula ABX<sub>3</sub>, in which A = CH<sub>3</sub>NH<sub>3</sub><sup>+</sup>, CH(NH<sub>2</sub>)<sub>2</sub><sup>+</sup>; B = Pb<sup>2+</sup>, Sn<sup>2+</sup>; and X = I<sup>-</sup>, Br<sup>-</sup>, Cl<sup>-</sup>) has seen dramatic growth in the past 7 years, yielding an increase in power conversion efficiency from 3.8 % in 2009<sup>1</sup> to 22.1 % in 2016.<sup>2</sup> One limiting factor in the commercial development of complete perovskite solar cells is the high cost of the hole-transport material (HTM).<sup>3</sup> The HTM is a p-type semiconductor layer that extracts positive charges (holes) from the perovskite absorber and transfers them to the back contact. Currently, the most efficient perovskite solar cells use the HTM 2,2',7,7'-tetrakis(*N,N*-di-*p*-methoxyphenylamine)-9,9'-spirobifluorene (spiro-OMeTAD), the synthesis of which is complex and requires extensive, costly purification.<sup>4</sup> The spiro-OMeTAD HTM is usually deposited by spin coating, which typically incorporates only ca. 5% of the expensive starting material<sup>5</sup> and produces nonconformal films.<sup>6</sup> To compensate for this lack of conformality, a HTM of spiro-OMeTAD must be at least 150 nm thick to prevent shunting between the absorber and the back contact of the cell.<sup>7</sup> In contrast, inorganic HTMs can be deposited by vacuum techniques that require significantly less material to fully coat an underlying surface. Indeed, a solar cell with a power conversion efficiency greater than 10 % can be produced using only 5 nm of an inorganic HTM.<sup>8</sup> It is clear that the current usage of a thick and prohibitively expensive organic HTM is far from ideal.

The development of a suitable alternative to the spiro-OMeTAD HTM is imperative for the commercial development of perovskite photovoltaics.

One class of materials that might provide an inexpensive HTM is copper(I) halides. Cuprous iodide (CuI) has been used successfully in a perovskite solar cell,<sup>9,10</sup> with devices exhibiting power conversion efficiencies of up to 13.6 %.<sup>11</sup> Cuprous bromide (CuBr) also shows promise: it is a p-type semiconductor with a hole concentration on the order of  $10^{16} \text{ cm}^{-3}$  and a hole mobility of  $0.4 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ .<sup>12</sup> The p-type conductivity is thought to originate from copper vacancies and oxygen doping.<sup>12</sup> CuBr features a wide bandgap of 2.9 eV, which would prevent parasitic light absorption during use in a solar cell.<sup>13</sup> Films of CuBr have been deposited previously by vacuum evaporation,<sup>14</sup> molecular beam epitaxy,<sup>15</sup> and r.f. sputtering.<sup>16</sup>

Chemical vapor deposition (CVD) is a more appealing growth process for HTMs because it can produce films with high thickness uniformity and conformality over large areas of deposition. However, metal fluorides are the only halide compounds with known CVD growth processes.<sup>17-19</sup> Previous research in this lab indicates that direct CVD of metal halides is not well controlled when highly acidic hydrogen halide precursors (HX, with X = Cl, Br, I) are used. The reaction between HX and a metalorganic precursor does in fact produce the desired metal halide material by transferring a proton from HX to the anionic ligand of the metalorganic precursor, thereby releasing the neutral form of the ligand to be evacuated. However, CVD processes continuously supply both precursor vapors, allowing excess HX to protonate the newly released ligand a second time if that free ligand is basic. This acid-base reaction forms a ligand-hydrogen halide salt that is incorporated into the resultant film. For example, X-ray photoelectron spectroscopy

(XPS) performed on nominal CuBr deposited by pulsed-CVD reveals carbon and nitrogen contamination consistent with the acetamidinium bromide salt (Fig. S1 in Supplementary Materials).<sup>20</sup>

Atomic layer deposition (ALD) is a type of CVD that separates the introduction of precursor vapors by purging with an inert gas and evacuating after each exposure. ALD is known as “self-limiting” because film growth proceeds by cycles of alternating precursor exposures and continues in each cycle only until surface reactive sites are depleted.<sup>21</sup> It seems plausible that pure metal halide films could be deposited by this method given that the sequential nature of ALD would prevent the exposure of a basic ligand to a strong hydrogen halide acid. However, in an ideal ALD sequence, the hydrogen halide exposure step produces a halide-terminated surface, which means that no surface reactive sites are available for the next cycle of metalorganic precursor exposure. This limitation could be overcome if either the hydrogen halide or the metal precursor were able to adsorb to the film surface strongly enough to remain through the purge and evacuation steps. Previous research in this lab demonstrating the failure of ALD to produce any film under a variety of conditions indicates that this strong adsorption does not occur for the copper compound bis(*N,N'*-di-*sec*-butylacetamidinato)dicopper(I), [Cu(*s*Bu<sub>2</sub>AMD)]<sub>2</sub>. With regard to hydrogen halides, it has been shown that strong adsorption on metal halide surfaces occurs only for HF, as a result of the formation of bifluoride (FHF<sup>-</sup>) anions on the surface.<sup>22</sup> Adsorption of other hydrogen halides to a metal halide film is too weak to bind the molecule to the surface during purging and evacuation.<sup>22</sup> As such, we see no direct route to ALD of metal halides (with the exception of fluorides) using metalorganic precursors and hydrogen halide reactants.

Given the obstacles to the direct deposition of metal halides by CVD or ALD, the development of an alternative method for vapor deposition of CuBr and other halides is needed. Here, a novel route to the vapor deposition of pure CuBr by a two-step process is presented. A film of Cu<sub>2</sub>S is first deposited by a pulsed-CVD reaction between [Cu(*s*Bu<sub>2</sub>AMD)]<sub>2</sub> and hydrogen sulfide.<sup>23</sup> This film is then exposed to anhydrous hydrogen bromide gas while held at a temperature of 60 °C. XPS reveals that the HBr exposure is able to fully convert at least 100 nanometers of the deposited Cu<sub>2</sub>S to CuBr. Structural and morphological properties of the resultant CuBr films are presented and discussed.

## II. EXPERIMENTAL

### A. *Film growth*

Cu<sub>2</sub>S and CuBr films were grown in a custom-built, hot-walled ALD reactor similar in design to those described in previous work.<sup>24</sup> Films were deposited on 1'' × 1'' substrates of Si with a 300-nm surface layer of SiO<sub>2</sub> grown by wet oxidation. Substrates were sequentially rinsed in semiconductor-grade acetone and isopropanol (BDH, ≥ 99 %) and then dried in a nitrogen gas stream. The substrates were then treated with UV-ozone for 5 minutes to promote the formation of surface hydroxyl groups.

Thin films of Cu<sub>2</sub>S were deposited via pulsed-CVD using exposures to [Cu(*s*Bu<sub>2</sub>AMD)]<sub>2</sub> (Dow Chemical Company, synthesis first reported by Li *et al.*<sup>25</sup>) and H<sub>2</sub>S (Airgas, 4 wt. % in N<sub>2</sub>). Both precursors were used as received and the [Cu(*s*Bu<sub>2</sub>AMD)]<sub>2</sub> was loaded into a vacuum bubbler under a nitrogen atmosphere to prevent decomposition in air. The [Cu(*s*Bu<sub>2</sub>AMD)]<sub>2</sub> vapor was transferred to the reactor chamber by a purified nitrogen carrier gas held at a pressure of 10 Torr in the bubbler.

The  $[\text{Cu}(\text{sBu}_2\text{AMD})]_2$  and  $\text{H}_2\text{S}/\text{N}_2$  reactants were mixed together in a region 1'' in length and 0.57'' in diameter before reaching the substrate holder. Swagelok ALD valves operated by LabView executed the pulsed-CVD recipes. Pulsed-CVD is similar to ALD, but omits the purging step between precursor doses. The timing sequence used for the  $\text{Cu}_2\text{S}$  recipe may be expressed as  $t_1-t_2-t_3-t_4-t_5$ , where  $t_1$  is the exposure time of the  $[\text{Cu}(\text{sBu}_2\text{AMD})]_2$  precursor,  $t_2$  is the exposure time of the  $\text{H}_2\text{S}/\text{N}_2$  mixture,  $t_3$  is a waiting period during which all valves are closed and deposition occurs,  $t_4$  is the nitrogen purge time, and  $t_5$  is the evacuation time, with all times given in seconds. The timing sequence was 1-1-30-10-30 for all  $\text{Cu}_2\text{S}$  depositions.  $[\text{Cu}(\text{sBu}_2\text{AMD})]_2$  was delivered at a partial pressure of 0.025 Torr for a total exposure of 0.85 Torr-sec and the  $\text{H}_2\text{S}/\text{N}_2$  mixture was delivered at a pressure of 2.6 Torr for a total  $\text{H}_2\text{S}$  exposure of 3.2 Torr-sec. The bubbler temperature of  $[\text{Cu}(\text{sBu}_2\text{AMD})]_2$  was maintained at 130 °C while the substrate temperature was varied from 100-200 °C. The inlet and outlet of the reactor tube furnace were heated to temperatures from 100-150 °C by Omega FGH heating tape regulated by an Omega miniature benchtop proportional-integral-derivative controller.

After completion of the  $\text{Cu}_2\text{S}$  deposition, the films were removed from the reactor and the substrate temperature was adjusted to 30 °C, 60 °C, or 180 °C. Half of the as-deposited films were stored under  $\text{N}_2$  atmosphere for future characterization and half were returned to the reactor after a brief (ca. 5 minutes) air exposure. At this point, conversion to  $\text{CuBr}$  proceeded via repeated exposures to anhydrous  $\text{HBr}$  (MilliporeSigma,  $\geq 99\%$ , used as received). The  $\text{HBr}$  was introduced by a 1-second pulse at a pressure of 1.3 Torr followed by a 30-second wait period with all valves closed. The total  $\text{HBr}$  exposure was 36 Torr-sec. This was followed by a 10-second  $\text{N}_2$  purge and 30-

second evacuation. The repeated purging and evacuation steps were implemented to ensure the removal of generated  $\text{H}_2\text{S}$  and the continuation of the forward conversion reaction. The number of cycles was typically 484, which corresponds to about 4 hours of total exposure to  $\text{HBr}$ . Although the films do not appear to oxidize or hydrolyze in air, all as-deposited and converted samples were stored under  $\text{N}_2$  atmosphere except during analysis.

### ***B. Film characterization***

Electron microscopy and energy dispersive X-ray spectroscopy (EDS) were performed in a Zeiss Supra 55 scanning electron microscope (SEM). X-ray diffraction (XRD) patterns were recorded in a Bruker D2 PHASER X-ray diffractometer using  $\text{Cu K}\alpha$  radiation ( $\lambda = 1.542 \text{ \AA}$ ) and a  $\theta$ - $2\theta$  scan. X-ray photoelectron spectroscopy (XPS) was performed on a Thermo Scientific K-Alpha spectrometer equipped with a monochromatized  $\text{Al K}\alpha$  X-ray source, 12 kV electron beam, and  $\text{Ar}^+$  sputtering gun. Depth profiles were collected by sputtering at 500 eV for 50 seconds per level, unless otherwise stated. The XPS sputtering rate was determined by dividing the film thickness as determined by SEM by the total sputtering time before the  $\text{SiO}_2$  substrate was detected.

## **III. RESULTS AND DISCUSSION**

### ***A. $\text{Cu}_2\text{S}$ growth***

The growth of  $\text{Cu}_2\text{S}$  was optimized across several variables with the ultimate goal of producing a pure, continuous film of uniform thickness. Pulsed-CVD was chosen as the deposition method for its accelerated growth rate relative to ALD.<sup>26</sup> XPS survey

spectra reveal that depositions conducted between 120 °C and 180 °C produced films containing solely copper and sulfur, whereas films deposited at 100 °C or 200 °C also contain carbon (Fig. S2 in Supplementary Materials).<sup>20</sup> As evidenced by electron micrographs, growth proceeds by island coalescence. Figures 1(a)-1(c) compare pulsed-

FIG. 1. (Color online) SEM images of  $\text{Cu}_2\text{S}$  film coverage after 322 cycles at a growth temperature of (a) 180 °C, (b) 150 °C, and (c) 120 °C. 120 °C was selected for its superior film coverage and  $\text{Cu}_2\text{S}$  films were deposited for (d) 400 and (e) 500 cycles. A high-resolution XPS scan of the  $\text{Cu}2\text{p}$  region shown in (f) gives no indication of the  $\text{Cu}^{2+}$  satellite peak typically observed at 943 eV (highlighted region).

CVD  $\text{Cu}_2\text{S}$  films after 322 cycles of growth at 180 °C, 150 °C, and 120 °C, respectively. In these depositions, the temperature at the inlet of the reactor tube, ca. 1'' from the substrate, was set to 150 °C, 120 °C, and 100 °C, respectively. As the progression from Fig. 1(a) to Fig. 1(c) shows, surface coverage increases as substrate and inlet temperatures decrease. Of particular significance is Fig. 1(c), which demonstrates that the reaction between  $[\text{Cu}(\text{sBu}_2\text{AMD})]_2$  and  $\text{H}_2\text{S}$  proceeds even at the low temperature of 120 °C. This high reactivity implies that if the inlet of the reactor tube is heated to 120 °C or

greater, film deposition can occur in the mixing region before the precursors reach the substrate holder. As such, the observed reduction in surface coverage for higher growth temperatures likely results from significant film deposition in the mixing region, owing to the higher corresponding inlet temperature. Much of the delivered precursor is therefore consumed upstream of the SiO<sub>2</sub> substrates. The reaction proceeds more slowly at an inlet temperature of 100 °C, which limits the deposition in the mixing region and leads to higher surface coverage of Cu<sub>2</sub>S at a substrate temperature of 120 °C. High-quality films of Cu<sub>2</sub>S can also be grown more quickly at this temperature by pulsed-CVD with the waiting period  $t_3 = 1$  second, as well as by standard ALD.

Figures 1(d) and (e) show the morphology of Cu<sub>2</sub>S films deposited at 120 °C over 400 and 500 cycles, respectively. At this temperature, film closure occurs between 322 and 500 cycles and the growth per cycle ranges from 1.1 to 1.7 Å/cycle, with the higher values calculated from thicker films. This large variation in growth per cycle at a single temperature is likely due to a relatively higher amount of film deposited per cycle during steady-state Cu<sub>2</sub>S deposition as compared with initial nucleation. The existence of separate nucleation and bulk deposition growth regimes is relatively common in ALD and CVD processes.<sup>27-30</sup> Figure 1(f) is a high-resolution XPS spectrum of the Cu2p peak obtained after 45 seconds of Ar<sup>+</sup> sputtering. While C and O are detected at the surface of the deposited films, these contaminants are removed after 45 seconds of Ar<sup>+</sup> sputtering and the absence of the characteristic Cu<sup>2+</sup> satellite peak at 943 eV confirms copper is present as Cu<sup>+</sup> throughout the film.<sup>31</sup>

## **B. CuBr growth**

After optimization of the Cu<sub>2</sub>S growth process, experiments were conducted to convert the Cu<sub>2</sub>S film to pure CuBr. The deposited films of Cu<sub>2</sub>S were exposed to anhydrous HBr in accordance with the reaction described in Eq. (1).

This reaction is thermodynamically favorable with a  $\Delta G$  value of -40 kJ/mol at 60 °C (details of this calculation can be found in the Supplementary Materials).<sup>20</sup> Films of Cu<sub>2</sub>S with a range of thicknesses from 60 to 400 nm were first prepared. These films were then heated to 60 °C and exposed to 484 pulses of HBr at a pressure of 1.3 Torr, amounting to a total exposure time of 4 hours. The variation in atomic composition through the thickness of the converted films was measured by a depth profile within the XPS. Figure

FIG. 2. (Color online) Depth profile obtained by XPS of a film converted from a 400-nm thick film of Cu<sub>2</sub>S.

2 shows the incomplete conversion of a 400-nm thick film of Cu<sub>2</sub>S. As evidenced by the presence of Br, the HBr was able to penetrate through hundreds of nanometers of the film, fully converting the top 100 nm to CuBr (highlighted region). After this top 100 nm

is removed by sputtering, sulfur becomes detectable by XPS and the film transitions gradually to predominantly  $\text{Cu}_2\text{S}$ . Oxygen and silicon from the  $\text{SiO}_2$  substrate become visible after the full 400-nm thickness is removed. The forward reaction in Eq. (1) is slightly more exergonic at 30 °C ( $\Delta G = -42$  kJ/mol) and does proceed, but the penetration depth of the HBr is shallower, with 9 hours of exposure resulting in only 25 nm of CuBr at the surface (Fig. S3 in Supplementary Materials).<sup>20</sup>

Conversion of  $\text{Cu}_2\text{S}$  to CuBr is further evidenced by XRD analysis before and after HBr exposure. Figure 3 presents the diffractograms of the as-deposited  $\text{Cu}_2\text{S}$  film and the same film after a 4-hour exposure to HBr at 60 °C. Figure 3(a) shows that the as-

FIG. 3. (Color online) X-ray diffraction patterns of as-deposited 250 nm thick  $\text{Cu}_2\text{S}$  film (top) and the same film after conversion of the top 100 nm to CuBr via a 4-hour exposure to HBr at 60 °C (bottom). The asterisk (\*) denotes a background peak associated with the XRD instrument itself.

deposited  $\text{Cu}_2\text{S}$  films are crystalline and highly-oriented. The experimental pattern best matches PDF 53-0522 for cubic  $\text{Cu}_2\text{S}$ , though the expected crystal structure for  $\text{Cu}_2\text{S}$  formed at 120 °C is the hexagonal high-chalcocite.<sup>32</sup> This discrepancy may be due to the significant impact of small deviations in stoichiometry on the resultant crystal structure of

$\text{Cu}_2\text{S}$  films, which complicates the precise crystallographic analysis of this material by XRD.<sup>33</sup> Figure 3(b) illustrates the measured XRD pattern of the same  $\text{Cu}_2\text{S}$  film following the HBr exposure, which matches PDF 006-0292 for  $\gamma\text{-CuBr}$ . Both the as-deposited and converted films appear to be (111)-oriented.

The film morphology was also influenced by the duration and temperature of the HBr exposures. HBr exposure tests were conducted at 30 °C, 60 °C, and 180 °C with a

FIG. 4. SEM images of  $\text{Cu}_2\text{S}$  films with initial thickness  $x$ , exposed to HBr for  $y$  hours at a temperature of  $z$  °C (denoted  $x$ - $y$ - $z$ ) (a) 400 nm-4 hrs-60 °C; (b) 400 nm-4 hrs-180 °C; (c) 400 nm-10 hrs-60 °C; (d) 400 nm-10 hrs-60 °C imaged in cross-section; (e) 60 nm-4 hrs-60 °C; (f) 60 nm-10 hrs-60 °C.

total exposure time of either 4 or 10 hours. These two parameters control the extent of the conversion. The use of longer HBr exposures or higher reaction temperatures resulted in a greater volume of  $\text{Cu}_2\text{S}$  converted to CuBr. Electron micrographs in Fig. 4 show the variation in film morphology produced by these changes in exposure conditions. For shorter HBr exposure times or lower reaction temperatures, the converted CuBr formed as a surface layer that appeared rougher than the as-deposited  $\text{Cu}_2\text{S}$ , but remained continuous. However, for longer exposures or higher reaction temperatures, the conversion of  $\text{Cu}_2\text{S}$  progressed farther into the film and two distinct morphologies developed. The SEM image in Fig. 4(b) illustrates these morphologies. The upper layer is comprised of uncoalesced, 1  $\mu\text{m}$ -sized grains, and the layer beneath is made up of 200-nm grains. Both layers are discontinuous, though the large grains of the top layer are more spatially separated than the smaller grains underneath. Figure 4(f) shows a similar discontinuous morphology, except the grains of the top layer are smaller. Two-dimensional EDS mapping shown in Fig. 5 confirms that the larger grains at the surface

FIG. 5. (Color online) EDS composition mapping of a 400-nm thick film of  $\text{Cu}_2\text{S}$  exposed to HBr for 4 hours at 180 °C.

are composed of copper and bromine, whereas the smaller grains beneath are composed of copper and sulfur. The SiO<sub>2</sub> substrate is also visible through the converted film.

The thickness of the as-deposited Cu<sub>2</sub>S affects the morphology of the converted CuBr. Figures 4(c) and (f) show films of Cu<sub>2</sub>S with different initial thicknesses that have been exposed to HBr for 10 hours at 60 °C. The 400-nm thick film of Fig. 4(c) has a smooth, continuous surface of CuBr (visible in cross-section in Fig. 4(d)), whereas the 60-nm thick film of Fig. 4(f) has developed the discontinuous morphology. Table 1 contains the atomic composition of the films imaged in Fig. 4 as determined by XPS survey spectra conducted after 30 seconds of Ar<sup>+</sup> sputtering. The surface of the film imaged in Fig. 4(c) is exclusively composed of copper and bromine, whereas for the film in Fig. 4(f), copper and bromine are detected, but also sulfur and the silicon and oxygen of the SiO<sub>2</sub> substrate. From these results, it appears that the conversion of Cu<sub>2</sub>S to CuBr upon exposure to HBr proceeds until enough of the Cu<sub>2</sub>S is consumed that the SiO<sub>2</sub> surface is exposed. At this point, the CuBr agglomerates into larger grains on the surface of the remaining Cu<sub>2</sub>S. This result suggests that the surface energy of the partially converted film is minimized when CuBr-Cu<sub>2</sub>S and CuBr-CuBr interactions are favored over CuBr-SiO<sub>2</sub> interactions. Thinner as-deposited films of Cu<sub>2</sub>S require shorter HBr exposures and lower reaction temperatures to develop the discontinuous morphology, which is consistent with this hypothesis, as there is less Cu<sub>2</sub>S to convert before the SiO<sub>2</sub> surface is exposed. Research is ongoing to find a substrate that will allow a film of Cu<sub>2</sub>S to be converted completely to a thin, continuous film of CuBr.

As-deposited thickness (nm)	Exposure duration (hours)	Exposure temperature (°C)	Cu (at.%)	Br (at.%)	S (at.%)	Si (at.%)	O (at.%)
400	4	60	54	46			
400	4	180	45	35	14	2.5	4.5
400	10	60	56	45

60	10	60	41	9	29	11	10

TABLE 1. As-deposited Cu<sub>2</sub>S film thicknesses and subsequent HBr exposure parameters. Elemental composition was measured by XPS survey spectra after 30 seconds of Ar<sup>+</sup> sputtering.

## IV. SUMMARY AND CONCLUSIONS

Thin films of CuBr were deposited by a two-step process, starting with the growth of Cu<sub>2</sub>S by pulsed-CVD of bis(*N,N'*-di-*sec*-butylacetamidinato)dicopper(I) and hydrogen sulfide at temperatures ranging from 100 °C to 200 °C. A growth temperature of 120 °C produced crystalline Cu<sub>2</sub>S films with carbon and oxygen contents below the detection limit of XPS. These Cu<sub>2</sub>S films were then converted to CuBr by exposure to anhydrous hydrogen bromide at 60 °C. The reaction produced films of pure, crystalline (111)-oriented  $\gamma$ -CuBr. The morphology of the resultant CuBr was dependent on the proximity of the growth front to the SiO<sub>2</sub> substrate, with much larger grains forming in a discontinuous arrangement when the substrate was exposed. This sulfide-to-bromide conversion process is in principle generalizable to the preparation of halides of many different metals, thereby extending the potential scope of halide CVD beyond solely metal fluorides.

Table

As-deposited thickness (nm)	Exposure duration (hours)	Exposure temperature (°C)	Cu (at.%)	Br (at.%)	S (at.%)	Si (at.%)	O (at.%)
400	4	60	54	46			
400	4	180	45	35	14	2.5	4.5
400	10	60	56	45			
60	4	60	54	46			
60	10	60	41	9	29	11	10

## Figure Captions

FIG. 1. (Color online) SEM images of  $\text{Cu}_2\text{S}$  film coverage after 322 cycles at a growth temperature of (a) 180 °C, (b) 150 °C, and (c) 120 °C. 120 °C was selected for its superior film coverage and  $\text{Cu}_2\text{S}$  films were deposited for (d) 400 and (e) 500 cycles. A high-resolution XPS scan of the  $\text{Cu}2p$  region shown in (f) gives no indication of the  $\text{Cu}^{2+}$  satellite peak typically observed at 943 eV (highlighted region).

FIG. 2. (Color online) Depth profile obtained by XPS of a film converted from a 400-nm thick film of  $\text{Cu}_2\text{S}$ .

FIG. 3. (Color online) X-ray diffraction patterns of as-deposited 250 nm thick  $\text{Cu}_2\text{S}$  film (top) and the same film after conversion of the top 100 nm to  $\text{CuBr}$  via a 4-hour exposure to  $\text{HBr}$  at 60 °C (bottom). The asterisk (\*) denotes a background peak associated with the XRD instrument itself.

FIG. 4. SEM images of  $\text{Cu}_2\text{S}$  films with initial thickness  $x$ , exposed to  $\text{HBr}$  for  $y$  hours at a temperature of  $z$  °C (denoted  $x$ - $y$ - $z$ ) (a) 400 nm-4 hrs-60 °C; (b) 400 nm-4 hrs-180 °C; (c) 400 nm-10 hrs-60 °C; (d) 400 nm-10 hrs-60 °C imaged in cross-section; (e) 60 nm-4 hrs-60 °C; (f) 60 nm-10 hrs-60 °C.

FIG. 5. (Color online) EDS composition mapping of a 400-nm thick film of  $\text{Cu}_2\text{S}$  exposed to  $\text{HBr}$  for 4 hours at 180 °C.

TABLE 1. As-deposited  $\text{Cu}_2\text{S}$  film thicknesses and subsequent  $\text{HBr}$  exposure parameters. Elemental composition was measured by XPS survey spectra after 30 seconds of  $\text{Ar}^+$  sputtering.
